## Abstract

**Purpose:** Stress responses in athletes can be attributed to training and also competition, where increased physiological and psychological stress may negatively impact on performance and recovery. The aim of this study was to examine the relationship between training load and salivary biomarkers IgA, alpha-amylase (AA) and cortisol across a 16-week preparation phase and 10-day competition phase in Paralympic swimmers. **Methods:** Four Paralympic swimmers provided bi-weekly saliva samples during three training phases – 1) normal training, 2) intensified training and 3) taper as well as daily saliva samples in the 10 day Paralympic competition (2016 Paralympic Games). Training load (TL) was measured using session-RPE. **Results:** Multi-level analysis identified a significant increase in sIgA (94.98 (27.69)  $\mu\text{g.ml}^{-1}$ ), sAA (45.78 (19.07)  $\mu\text{g.ml}^{-1}$ ) and salivary cortisol (7.92 (2.17) ng.ml) during intensified training concurrent with a 38.3% increase in TL. During taper phase, a 49.5% decrease in TL from the intensified training phase resulted in decrease in sIgA, sAA and salivary cortisol; however, all three remained higher than baseline levels. A further significant increase was observed during competition in sIgA (168.69(24.19)  $\mu\text{g.ml}^{-1}$ ), sAA (35.86(16.67)  $\mu\text{g.ml}^{-1}$ ) and salivary cortisol (10.49(1.89) ng.ml) despite a continued decrease (77.8%) in TL from taper phase. **Conclusions:** Results demonstrate performance in major competition such as Paralympic Games despite a noticeable reduction in TL induces a stress response in athletes. Due to elevated stress response observed, modifications to individual post-race recovery protocols may be required to enable athletes to maximise performance across all ten days of competition.

## 73 **Introduction**

74 Athletic training is based on the principle of progressive  
 75 overload where increased training stressors combined with  
 76 appropriate recovery are employed to produce a positive  
 77 training adaptation.<sup>1</sup> Included in a periodised pre-competition  
 78 preparation plan is a period of intensified training followed by a  
 79 taper phase where training volume is typically reduced whilst  
 80 maintaining or even increasing intensity resulting in positive  
 81 adaptation and performance enhancements.<sup>2</sup> However,  
 82 responses to athletic stress are highly individualised with  
 83 athletes recovering from the same training stimulus  
 84 differently.<sup>3</sup> Whilst the taper period is designed to reduce  
 85 training stress and promote recovery, performance in athletic  
 86 competition has been shown to induce a psychophysiological  
 87 stress response irrespective of the reduction in training load  
 88 (TL). Given the sensitivity of immune function to physiological  
 89 and psychological stressors, immune and stress salivary  
 90 biomarkers may assist in monitoring the athletic responses to  
 91 training and competition demands.<sup>4</sup>

92 Training load monitoring can be used to measure the individual  
 93 training stress for each athlete using physiological and  
 94 psychological variables, ensuring individualisation of training  
 95 prescription and minimising risk of overtraining.<sup>5</sup> Originally  
 96 proposed by Foster et al.,<sup>6</sup> the session rate of perceived  
 97 exertion (sRPE) method quantifies internal training load as an  
 98 arbitrary unit using an athletes RPE score multiplied with  
 99 training session duration in minutes. The sRPE method is  
 100 sufficiently accurate to measure training session intensity if HR  
 101 data is not available or a more practical method is required for  
 102 calculating training load.<sup>7</sup> It has also been shown to be a  
 103 reliable method of quantifying training load in water based  
 104 sports where heart rate is not easy collected having previously  
 105 been validated in swimmers.<sup>8</sup>

106 Salivary biomarkers are easily accessible and non-invasive  
 107 measures which can be quantified quickly and repeatedly.<sup>9</sup>  
 108 Saliva contains both immunity and stress biomarkers including  
 109 immunoglobulin A (IgA), alpha-amylase (sAA) and cortisol, all  
 110 of which have been shown to respond to training and  
 111 competition stress in athletes. IgA secreted in saliva, has a  
 112 primary role in defence against infection of the upper  
 113 respiratory tract, and has been established as a reliable  
 114 biomarker for identifying risk of infection in elite athletes.<sup>10</sup>  
 115 Previous research has reported an inverse relationship between  
 116 salivary IgA levels and incidence of illness in athletes<sup>11</sup>, while  
 117 changes in salivary IgA levels may also indicate periods of  
 118 excessive training or inadequate recovery.<sup>12</sup> Salivary alpha-  
 119 amylase (sAA) produced in the salivary glands has been shown

120 to be a reliable indicator of the response of the sympathetic  
121 nervous system to exercise.<sup>13</sup> This response appears to peak  
122 rapidly at the onset of a stressor before returning to baseline  
123 levels 30-60 minutes later<sup>14</sup> and this acute response has been  
124 associated with both physical and psychological  
125 stressors.<sup>15</sup> Salivary cortisol is secreted by the adrenal cortex in  
126 response to physical or psychological stress, and can provide a  
127 reference for cortisol levels in the blood with research showing  
128 more pronounced changes in saliva in response to exercise.<sup>9</sup>  
129 Cortisol levels have been shown to increase concurrently with  
130 training load in swimmers<sup>16</sup> while in rugby union players,  
131 increases were observed following an international level game  
132 and remained elevated above pre-game levels fourteen hours  
133 later.<sup>17</sup> Regular monitoring of controlled resting levels of  
134 salivary biomarkers has been recommended to determine  
135 individual reference data as variations within and between  
136 subject groups implies that the stress response to training load,  
137 competition and additional external stressors is highly  
138 individual.<sup>10</sup>

139 Despite the shift in focus from rehabilitative participation to  
140 elite level sport, research into Paralympic sport has lagged  
141 behind the large body of scientific investigation of able-bodied  
142 athletes. Training load and athletic response must be monitored  
143 in a bid to fully understand the training and recovery needs of  
144 this highly individual athletic population. Therefore the aim of  
145 this study is to examine the training loads and salivary  
146 biomarker responses during preparation and competition in four  
147 Paralympic swimmers.

## 148 **Methods**

### 149 ***Participants***

150 Four elite Paralympic swimmers (1 male, 3 female, age  $19 \pm$   
151  $4$  yrs, body mass  $48.5 \pm 7.6$  kg) selected for competing at Rio  
152 2016 Paralympic Games participated in this study. Details of  
153 individual training age, impairment type and swimming  
154 classification are presented in Table 1. A typical training week  
155 consisted of seven to nine pool sessions of two hour duration  
156 each (14-18 hours weekly) and two gym sessions of one hour  
157 duration (2 hours weekly). Individual swimming programs  
158 were prescribed dependent upon swimming class; with higher  
159 classed swimmers completing the higher training hours. The  
160 athletes had been competing regularly in international  
161 competitions for at least 3 years. All four athletes had competed  
162 and reached finals in the World Championships in the previous  
163 12 months. Testing protocols formed part of the on-going  
164 physiological support programme which swimmers were  
165 familiar with before participation in this study. All participants  
166 were fully informed of the requirements and potential risks and  
167 benefits of participating with a written informed consent  
168 completed before commencement of data collection. All

169 experimental procedures were approved by University of  
170 Limerick Ethics Committee.

### 171 ***Experimental Design***

172 Athletes were monitored throughout a twelve month period in  
173 the run-up to the 2016 Paralympic Games. Four periods of  
174 collection were established in the 16 weeks before the  
175 Paralympic Games: 1) a baseline non-competition period of 4  
176 weeks (11 samples), 2) an intensified training period of 2  
177 weeks (6 samples), 3) a taper of 10 days (4 samples) and 4) a  
178 competition period of 10 days (10 samples). No samples were  
179 collected during the first seven days upon arrival in Brazil in  
180 order to reduce any impact of travel fatigue and jet lag on  
181 salivary biomarker response. During the non-competition  
182 periods, salivary data was collected twice weekly to determine  
183 a baseline hormonal profile whilst daily samples were made  
184 each morning during the Paralympic Games competition,  
185 reflecting both race and resting day measures, to depict the  
186 salivary hormone response when competition stress would be  
187 highest.

188

### 189 ***Data Collection***

190 *Salivary Biomarkers.* Saliva samples were collected in the  
191 morning, 30 minutes after waking, before breakfast and before  
192 any physical exercise had been undertaken. Sampling was kept  
193 to a consistent one hour time block for each athlete to minimise  
194 impact of circadian variation on salivary biomarkers.  
195 Swimmers were instructed not to brush their teeth before  
196 providing the saliva sample. Salivary samples were collected  
197 using an IPRO (Soma Bioscience, Wallingford, UK) oral fluid  
198 collector (OFC) kits. The ease of sample collection using the  
199 IPRO OFC kits allowed athletes to collect their saliva sample at  
200 home. The sampling protocol was followed in accordance with  
201 manufacturer's guidelines. The OFC is placed in the mouth and  
202 collects 0.5mL of saliva in one sample. A volume indicator  
203 within the swab handle changed colour to indicate when  
204 sufficient saliva volume has been collected. The swab was then  
205 removed from the mouth and placed into the IPRO OFC buffer.  
206 The duration of collection time was less than 60s. The buffer  
207 contains extraction agents to draw the target analytes from the  
208 swab into the buffer. Samples were analysed using an IPRO  
209 lateral flow device (LFD) with separate cartridges used to  
210 analyse IgA/AA and cortisol. The LFD has previously been  
211 validated against ELISA analysis ( $r = 0.89$ ,  $p < 0.01$  and  $CV =$   
212  $9.4\%$ ).<sup>15</sup> Two drops of buffer mix from the collector kit were  
213 added to the sample window on the LFD cartridges. After a  
214 standing time of 10 minutes, sample intensity is measured in an  
215 IPRO LFD reader and a quantitative value given.

216

217           *Training Load.* The session-RPE method was used to  
218 calculate training load as proposed by Foster et al.<sup>6</sup> Fifteen  
219 minutes after every training session<sup>19</sup> swimmers were asked to  
220 rate the intensity of the session using the CR-10 RPE scale.<sup>20</sup>  
221 The total session duration including warm-up and cool-down  
222 was recorded in minutes and multiplied by the RPE score given  
223 by each athlete (training load = duration x intensity). Training  
224 load is expressed in arbitrary units (AU).

### 225 *Statistical Analysis*

226 Mean and standard error were calculated for training load,  
227 salivary IgA, alpha-amylase and cortisol levels collected during  
228 the four training phases. Data was analysed using multilevel  
229 modelling approach using Multilevel Models Project MLn<sup>21</sup> to  
230 investigate longitudinal (repeated measures) data. Multilevel  
231 analysis is an extension of multiple regression. A random  
232 intercept model with 2 levels was created for IgA, AA and  
233 cortisol separately – time (level 1) nested within athlete (level  
234 2). Analysis was used to identify changes in mean values of  
235 three salivary biomarkers across the four identified time  
236 periods.

237

### 238 **Results**

239 Figure 1 shows mean  $\pm$  SE values for training load and salivary  
240 biomarker levels at each training phase (1 = baseline, 2 =  
241 intensified training, 3 = taper, 4 = competition).

242 The multi-level analysis (Table 2) identified a significant  
243 increase in levels of sIgA (94.98 (27.67)  $\mu\text{g.ml}^{-1}$ ), sAA (45.88  
244 (19.07)  $\mu\text{g.ml}^{-1}$ ) and salivary cortisol (7.92 (2.17) ng.ml) from  
245 baseline to intensified training. Increases were concurrent with  
246 a 38.3% increase in training load during this period.

247 During taper phase, a 49.5% decrease in the training load from  
248 the intensified training phase resulted in a decrease of sIgA,  
249 sAA and salivary cortisol levels. However, all three biomarker  
250 levels remained higher than baseline levels.

251 A further significant increase from baseline was observed  
252 during competition phase in sIgA (168.69(24.19)  $\mu\text{g.ml}^{-1}$ ), sAA  
253 (35.87(16.67)  $\mu\text{g.ml}^{-1}$ ) and salivary cortisol (10.49(1.89)  
254 ng.ml). Increases in all three biomarkers occurred despite a  
255 continued decrease of 77.8% in training load from taper phase.

256 Minimal changes between rest and race day levels of sIgA  
257 (380.62  $\mu\text{g.ml}^{-1}$  vs 379.77  $\mu\text{g.ml}^{-1}$  respectively) were observed.  
258 In contrast, race day induced an acute significant increase in  
259 salivary cortisol (-7.19(2.07) ng.ml) and sAA (-55.82(17.57)  
260  $\mu\text{g.ml}^{-1}$ ) compared to rest day, further demonstrating an  
261 elevated stress response associated with participating in a  
262 Paralympic Games.

## 264 **Discussion**

265 The present study was designed to examine training load and  
 266 the associated stress response through the measurement of three  
 267 salivary biomarkers in Paralympic swimmers during training  
 268 and performance in major competition. Salivary IgA, AA and  
 269 cortisol were shown to respond to changes in training load  
 270 across the training season. During a period of intensified  
 271 training, a 38.3% increase in training load was associated with  
 272 significant increases in all three salivary markers while a  
 273 subsequent decline in training load of 49.5% during a taper  
 274 phase coincided with decreases in sIgA, sAA and salivary  
 275 cortisol. Interestingly despite a further 77.8% reduction in  
 276 training load compared to the taper phase, during the  
 277 Paralympic Games salivary biomarkers were significantly  
 278 increased from baseline demonstrating an induced stress  
 279 response in all four Paralympic swimmers.

280 The emergence of a validated point of care test for sIgA and  
 281 sAA has allowed the quick analysis of salivary biomarkers.<sup>22</sup>  
 282 Furthermore it has been suggested cortisol changes in response  
 283 to exercise may be more pronounced in saliva compared to  
 284 blood as salivary cortisol represents biologically active, free  
 285 fraction of blood cortisol.<sup>23</sup> Thus salivary biomarkers have  
 286 emerged as a popular monitoring tool in athletic populations  
 287 due to the ease of use and non-invasive method of sample  
 288 collection. Research suggests that athletes undertaking  
 289 intensive and prolonged training may be at a higher risk of  
 290 upper respiratory tract infections (URTI).<sup>24</sup> Representing the  
 291 body's first line of defence against URTI, monitoring immune  
 292 function through sIgA levels can determine the effect of  
 293 exercise on mucosal immunity.<sup>9</sup> Longitudinal studies amongst  
 294 elite endurance athletes have shown sIgA levels to decrease in  
 295 response to increases in volume and duration of training, with a  
 296 decline appearing to contribute to the increased risk of illness in  
 297 athletes.<sup>10</sup> In contrast to this, findings from the current study  
 298 observed a significant increase from baseline in sIgA during  
 299 intensified training period correlating with a 38.3% increase in  
 300 training load. In a study investigating high school basketball  
 301 players, Tharp<sup>25</sup> reported a  $25.1\mu\text{g}\cdot\text{ml}^{-1}$  increase in mean sIgA  
 302 levels across a season and suggested chronic training may  
 303 result in increases in resting IgA levels providing further  
 304 protection from infection risk. Supporting this Gleeson and  
 305 Walsh<sup>26</sup> reported that moderate exercise can increase sIgA  
 306 concentrations thus decreasing the risk of URTI. The The four  
 307 athletes participating in the current study were 4-5 weeks away  
 308 from competition during the intense training camp after a long  
 309 training season and combined with sufficient recovery may  
 310 explain why no decreases occurred in sIgA. Following this, a  
 311 taper phase characterised by a gradual decrease in training

312 volume and increase in intensity resulted in a drop in overall  
313 training load and a subsequent decline in levels of sIgA. During  
314 this time declines in sAA and salivary cortisol were also  
315 observed.

316 Athletic competition has been shown to induce a stress  
317 response in athletes. sAA has been shown to be a reliable  
318 indicator of the adrenergic response to exercise<sup>13</sup> therefore can  
319 be measured alongside cortisol to depict the stress response to  
320 training and competition in a bid to optimise recovery.  
321 However, sAA has been reported to be a more sensitive  
322 measure to exercise-induced stress than cortisol as it does not  
323 require transport from blood to saliva.<sup>27</sup> sAA has been shown to  
324 significantly increase in response to competition with  
325 Kivlighan and Granger<sup>14</sup> reporting an increase of 156% during  
326 ergometer competition in male and female collegiate rowers.  
327 Findings from this study demonstrated a significant response in  
328 sAA levels during competition compared to baseline and are in  
329 line with those reported by Edmonds et al.<sup>22</sup> who observed a  
330 prolonged elevation in sAA following a weekend of elite level  
331 competition in disability swimmers. Furthermore Diaz et  
332 al.<sup>28</sup> compared sAA levels before and after a race event during  
333 competition and on a control day in swimmers and reported  
334 higher levels during competition which were attributed to  
335 increased psychological and physical stress. The increase in  
336 sAA in the current study during the competition phase can  
337 potentially be attributed to two stressors – an elevation from  
338 increased competition performance as well as the psychological  
339 stress of participating in a major competition.

340 Salivary cortisol has been extensively researched as an  
341 indicator of training stress. Gomes et al.<sup>29</sup> reported increases in  
342 training load and stress scores correlated with increases in  
343 salivary cortisol levels in tennis players during a periodised  
344 training programme before returning to baseline levels during a  
345 taper week. In line with these findings, we observed during the  
346 intensified training phase an increase in training load of 38%  
347 from baseline induced a stress response in athletes and resulted  
348 in a significant increase in salivary cortisol levels. Furthermore  
349 a decrease in salivary cortisol during the taper phase was  
350 accompanied by a decline in training load of 49.5%. However,  
351 further decreases in training load during the competition phase  
352 were not associated with additional declines in salivary cortisol  
353 levels. A study in soccer players showed a reduction in cortisol  
354 during recovery periods compared to periods of intense  
355 training.<sup>30</sup> The present study showed similar findings with a  
356 mean decrease in salivary cortisol levels during taper phase  
357 following an increase during the intensified training phase. In  
358 contrast salivary cortisol levels actually increased significantly  
359 again from baseline to their highest levels during the  
360 competition phase at a point where training loads were lowest.

361 The continued increase in salivary cortisol levels during this  
362 competition phase may be explained by an elevated  
363 psychological stress response induced by performance in a  
364 major competition such as the Paralympic Games.

365 A limitation of this study was the absence of a psychological  
366 assessment measure for example POMS or REST-Q to  
367 understand the stress impact on the athletes. However, similar  
368 to Moreira et al.<sup>31</sup> it is reasonable to suggest performance at a  
369 major international competition is a stressful situation for any  
370 athlete. A further limitation is the small sample size used in this  
371 case study, however, this accounts for the entire Paralympic  
372 swimming population of the Irish team and can therefore be  
373 regarded as being representative of the athletic population.

374

375

### 376 **Practical Applications**

377 The findings of this study suggest that coaches and support  
378 staff should recognise the stress response associated with  
379 participation in major competition despite training loads  
380 decreasing. According to Kellman<sup>32</sup> heightened stress levels in  
381 athletes can limit the ability to recover and require additional  
382 recovery activity. Our results indicate post-race recovery must  
383 account for not just the physiological stress on the body as a  
384 result of racing but also the individual physiological and  
385 psychological stress response to major competition. Additional  
386 recovery modalities, for example nutritional interventions,  
387 increased sleep and increased post-race swim down may be  
388 required to meet the increased recovery demand of athletes and  
389 assist in maximising performance across all ten days of  
390 competition.

### 391 **Conclusion**

392 This study aimed to examine the responses of sIgA, sAA and  
393 salivary cortisol to training and performance in competition.  
394 All three salivary markers were shown to respond to changes in  
395 training load with increases during more intense training and  
396 decreases during taper. Performance in major competition was  
397 shown to induce a further stress response in the athletes.  
398 Significant increases in sAA and salivary cortisol levels were  
399 observed during competition period compared to baseline  
400 despite low training loads. With a decrease in training load  
401 during this last phase it is reasonable to associate the response  
402 with increased psychological stress of participating in a  
403 competition as significant as a Paralympic Games.

### 404 **Acknowledgments**

405 We thank the head coach, manager and athletes from the Irish  
406 Paralympic swimming team for their participation in this study.  
407 This study was funded jointly by Sport Ireland Institute and  
408 Paralympics Ireland.

## 538 **Figure Captions**

539 **Figure 1:** Data mean  $\pm$  SE. Salivary IgA ( $\mu\text{g.ml}^{-1}$ ), salivary  
540 cortisol (ng.ml), salivary alpha-amylase ( $\mu\text{g.ml}^{-1}$ ) and training  
541 load across the four time points (1=baseline, 2=intensified  
542 training, 3=taper, 4=competition). \* indicates statistical  
543 significance between phase 1 and 2 determined by multi-level  
544 regression analysis. \*\* indicates statistical significance between  
545 phase 1 and 4 determined via multi-level regression analysis.

546 **Table 1:** Athlete characteristics. <sup>a</sup> IPC Classification code; <sup>b</sup> Years  
547 competing as part of the national Paralympic swim team

548

549 **Table 2:** Values are means  $\pm$  SE. Baseline training salivary  
550 levels were used as constant, indicated by (a) and compared to  
551 levels during three other training phases indicated by ( $\Delta$ a).  
552 Changes from baseline in all three salivary markers were  
553 significant at intensified training phase and again during  
554 competition phase. The between-subject variances (at level 2)

555 were not significant but the within subject variances (at level 1)  
556 were all significant.  
557

**Table 1. Athlete characteristics**

<b>Athlete</b>	<b>Gender</b>	<b>Disability Type</b>	<b>Swimming Class<sup>a</sup></b>	<b>Competition Experience (yrs)<sup>b</sup></b>
1	M	Les Autres	S5	5
2	F	Amputee	S9	9
3	F	Arthrogryposis	S8	4
4	F	Hypochondroplasia	S6	3

**Table 2. The multilevel regression analysis of salivary levels for the four athletes competing at the 2016 Paralympic games.**

	Salivary IgA		Salivary AA		Salivary Cortisol	
Fixed explanatory variables						
Parameter	Estimate	S. Error	Estimate	S. Error	Estimate	S. Error
Constant (a)	148.2	18.75	69.13	18.09	16.29	1.64
Intensified Training ( $\Delta$ a)	94.98	27.67	45.88	19.07	7.92	2.17
Taper ( $\Delta$ a)	25.58	31.62	29.73	21.79	1.97	2.48
Competition ( $\Delta$ a)	168.7	24.19	35.87	16.67	10.49	1.89
Random Variables						
Level 2 (between athletes)						
Variance	Estimate	S. Error	Estimate	S. Error	Estimate	S. Error
	220.3	430.9	745.63	653.91	3.47	4.14
Level 1 (within athletes)						
Variance	Estimate	S. Error	Estimate	S. Error	Estimate	S. Error
	11253.38	1497.1	5341.12	710.64	69.08	9.19
